

# Extension of the grazing period in spring in integrated arable crop—livestock systems

*This leaflet on the extension of the grazing period in systems combining arable crops and livestock is a part of a set of three leaflets, the first dealing with possible techniques in the spring, the second those of the summer and the third those of autumn. Each leaflet can be read separately.*

## 1 General context

Milk price has fluctuated a lot in recent years with, in addition, a downward trend. Beef meat price is also changing negatively. Therefore, reducing production costs becomes imperative to ensure the profitability of livestock systems. Grazed grass is the most 'natural' feed for domestic herbivores, and it is also the cheapest feed. Extending the grazing season is therefore an effective strategy for reducing production costs.

A well-managed and prolonged grazing in late winter-early spring and autumn also saves labour because the time spent on feeding animals and cleaning buildings is reduced. The saved time can be spent on leisure activities or on income-generating activities such as processing and marketing of products.

The climate crisis and its increasing summer droughts complicate the achievement of these objectives because they reduce grass production at this time of the year, especially that of permanent grasslands. It should therefore be possible to use new, more drought resistant mixtures, to ensure the continuity of grazing at this time of the year.

Grass-based dairy and meat products stand out from those produced on the basis of green maize and human foods (soybean, cereals). They have better nutritional qualities (lower levels of saturated fatty acids, better omega3/omega6 ratio, higher content of conjugated linoleic acid) and benefit from a more favourable image in the public.

Producing more grass-based milk and meat on mixed farms, combining arable crops and livestock farming, requires a combination of the following measures: a good grassland management, a complementarity between permanent grasslands and temporary grasslands, and an animal breed able to effectively transform grass into milk and meat.

### 2 Description of the innovation

In mixed farms, it is possible to integrate temporary grasslands into the rotation of annual crops. These grasslands are usually sown for periods of one to three years, for example with a mixture of grasses and legumes. These may be alfalfa/grass(es), red clover/grass(es) or more complex mixtures of several legumes and grasses.

Examples of mixtures:

- Alfalfa (20 kg/ha) – Cocksfoot (15 kg/ha) or cocksfoot (10 kg/ha) and tall fescue (5 kg/ha). Duration: 2 to 3 years or more.
- Diploid red clover (8 kg/ha) – Cocksfoot (15 kg/ha) or cocksfoot (10 kg/ha) and tall fescue (5 kg/ha). Duration: 1 to 2 years maximum with cultivars of the 'Ackerklee' type of red clover, 1 to 3 years maximum with cultivars of the 'Mattenklee' type of red clover.

The choice of cocksfoot and tall fescue is preferred because both species are drought resistant, which is favourable to summer growth. Diploid red clover cultivars are preferred because they are easier to dry than tetraploids.

Red clover and grass mixtures of temporary grasslands start their spring growth faster than permanent grasslands. Therefore, in late winter and early spring, the grazing season can be extended by grazing these temporary grasslands. Cuts are then harvested on these grasslands for stocking winter forage.

Grazing may stretch on two to three weeks, for example between March 15 and April 7 in North-West Europe. Soils are often sensitive to compaction at this time of the year, the passage of the animals must thus be fast so as not to damage soil structure and sward quality.

Instantaneous stocking rate must be important for quickly gathering forage and moving animals to the next surface. Grazing is organized by moving a front electric wire, twice a day or every day. Permanent fences are not necessary. Stocking rate is adapted to soil condition and the amount of available green forage. It is a good idea to give animals access to a rack filled with straw or low-quality hay so that they can regulate the water and protein contents of the ingested feed.

### 3 Results obtained with the adoption of the innovation

In regions where the housing period is approximately six months, reducing this period from two to three weeks corresponds to a reduction of 8 to 12% of the winter feed ration. This reduces the costs of concentrated feed and of preserved forage production in the same proportions.

Animal health is also improved because they do exercise.

## Technical leaflet

This innovation is well adapted to the Atlantic or continental climates of North-West Europe. In hyper-Atlantic climates (Ireland or Brittany, for example), where grass growth almost never stops, this system is less attractive although it is useful too. In climates with long, very cold winters (mountain areas, Scandinavia and Eastern Europe), the end of growth difference between temporary and permanent grassland is reduced, which decreases the interest of the technique.

This system is particularly suitable for farms integrating annual crops and livestock. It can be adapted to a 100% grass-based system provided that temporary grasslands are sown.

### Advantages

- lower feeding costs
- less manpower for animal feeding and building cleaning
- improved animal welfare
- better product quality

### Disadvantages

- It requires the daily movement of the electric wire which must sometimes be done by rainy and windy weather
- In the case of dairy cows, animals must also be brought back every day to the barn for milking
- Compared to a maize silage and concentrated feed ration, stocking requires more flexibility, observation and thought
